TYPE DESCRIPTION

A. Stand Composition

Red pine (*Pinus resinosa*) comprises 50% or more of the basal area in sawtimber and poletimber stands, or 50% or more of the stems in sapling and seedling stands. In mixed pine stands, red pine is predominant.

B. Associated Species

Many red pine stands are fairly pure with few associates. Pure natural stands typically originate following catastrophic fire. Red pine plantations often are established as monocultures. The most common associate within the red pine cover type is white pine (*Pinus strobus*). Other major associates are jack pine (*Pinus banksiana*), aspen (*Populus spp.*), and oak (*Quercus spp.*).

C. Soil Preference

The red pine cover type is most common on dry (excessively to somewhat excessively drained), nutrient poor to medium sands in historically fire-prone landscapes dominated by sandy outwash, lacustrine, or washed till deposits. Productivity can be good to excellent on many of these soils, but is only fair on the driest, most nutrient poor sands. Examples of soil characteristics that improve productivity (increase moisture and nutrient availability) are: finer textures (loamy sands), the presence of finer textured lenses or layers, underlying deposits (e.g. sand outwash over sandy loam till), and the presence of a water table at a depth of 4-9 feet. Red pine stands also occur on moist (moderately well to somewhat poorly drained) sands; productivity is generally good (to excellent), but decreases as soils become wetter.

Red pine plantations have been managed successfully on well drained to somewhat poorly drained loams and clays. On these moister and richer soils, natural stands sometimes occurred (historically) within landscapes where the fire regime was conducive to the regeneration and maintenance of red pine. Well drained (sandy) loams offer the greatest potential productivity.

Red pine generally does not grow well where the surface soil is alkaline (pH >6.5). Red pine stands generally do not survive and grow on poorly drained soils.

D. Range of Habitat Types

See Chapter 12 – Forest Habitat Type Classification System for information summarizing the system and the habitat type groups.
The red pine cover type occupies about 4% of statewide forest land acres (1996 FIA). It currently is more common in northern than in southern Wisconsin (Error! Reference source not found. and Error! Reference source not found.). Within the state, about 65% of red pine cover type acres and 73% of red pine net growing stock volume occur on northern habitat types. Southern Wisconsin habitat types contain about 35% of statewide red pine acres and 27% of the volume.

1. Northern Wisconsin Habitat Types
In northern Wisconsin, the occurrence and relative growth potential of the red pine cover type varies by habitat type groups and habitat types (Table 32.1 and Figure 32.3). Red pine is a common cover type on very dry to dry and dry to dry-mesic sites (habitat type groups); about 70% of the red pine cover type acres and 64% of the red pine volume in northern Wisconsin occur on these two groups. Red pine is a minor cover type on the dry-mesic, mesic, and mesic to wet-mesic habitat type groups. It generally does not occur on wet-mesic to wet sites.

2. Southern Wisconsin Habitat Types
In southern Wisconsin, the occurrence and relative growth potential of the red pine cover type varies by habitat type groups and habitat types (Table 32.2 and Figure 32.3). Red pine is a common cover type on dry sites; this habitat type group contains about 73% of the red pine cover type acres and 63% of the red pine volume in southern Wisconsin. Red pine plantations occur, but are uncommon, on most other habitat type groups in southern Wisconsin.

Red pine reaches its native range limit in southern Wisconsin (Error! Reference source not found. and
Figure 32.5). The only southern habitat type region entirely within the native range of red pine is region 9 (Error! Reference source not found.); in this region, the dry and dry-mesic habitat type groups are predominant. Habitat type regions 6, 7, and 8, in the western driftless region, occur at the historic western and southern limits of the natural range of red pine. Habitat type regions 10 and 11, in southeastern Wisconsin, are mostly out of range.

Plantations have been established in southern Wisconsin, outside of or near the natural range limits for red pine, on dry-mesic to mesic, nutrient rich, loamy soils. Long-term growth, productivity, and tree health are uncertain. Observations of plantation performance typically indicate excellent early growth. However, at comparatively young ages, anywhere between 20 and 60 years old, tree health and mortality problems often develop and stand growth slows or stagnates.

SILVICULTURAL CHARACTERISTICS*

Red pine is a native species adapted to a disturbance regime characterized by periodic ground fires and infrequent crown fires. It most commonly occurs on dry sands in historically fire-prone landscapes.

Red pine is considered genetically uniform, exhibiting relatively limited genetic variation throughout its geographic range.

Red pine is monoecious; female flowers are borne mostly in the middle third of the crown (in the upper third of the crown in older trees), and the purple male flowers are borne in the lower crown. Flowers are borne April to June, and pollination occurs May to June. Fertilization occurs in July the following year when cone growth is completed and the fully developed seed coats have hardened. Cones are about 0.5 inches long by late summer of the first year, and about 1.5-2 inches long when growth is completed. Cones are completely brown when they ripen late summer to early fall of the second year.

Good seed crops are produced every 3-7 years, with bumper crops only every 10-12 years. Seed production can be reduced by prolonged rainy weather at the time of pollination. Almost complete cone crop failure can occur due to insects, extreme weather, and other damaging agents between the first and second year of development. Cone production is stimulated by high temperatures during the spring and summer two years before cone maturation. The production of cones can be most prolific on branches that are thick, long, and young, and on the south side of the tree. Cone production per tree generally improves as stand density decreases; thinning can help increase cone production per tree.

Seed dispersal begins when the cones ripen. Cones open best on hot, still autumn days when there is little wind to carry the seeds far. During the first month, the heaviest most viable seeds fall. Most seeds are dispersed between September and November, but seed dispersal can continue throughout the winter and into the following summer. Most seeds fall to the ground within 40 feet, but can be disseminated up to 900 feet from the parent tree.

The ideal seedbed to facilitate germination is bare mineral soil, but light pine litter is acceptable. Germination occurs spring to early summer, and requires adequate moisture and warm temperatures (mostly 70-86°F). Factors facilitating the maintenance of moist seed include finer textured soils (e.g. loamy sand), thin moss, water table within 4 feet of the surface, light cover over the seed, and some shade. Germination can occur under dense brush, in heavy sod or litter, and in heavy ash, but seedlings generally do not develop or grow well. Other conditions known to inhibit germination include soil pH ≥8.5 and full sunlight for ≥4 hours per day. Both germination and early seedling survival are hindered by summer drought and high surface soil temperatures.

Red pine is shade intolerant. Seedlings can become established with 35% full sun, and grow well under 45% of full sun until age 5. Established seedlings grow best in (near) full sunlight, if other requirements are met. Red pine seedlings grow slowly, usually requiring 4-10 years to reach breast height. Height growth usually increases once seedlings/saplings are 5-10 years old, and dominance in dense stands is often expressed by age 12. Radial growth is related to precipitation in the current season.

During the first summer following germination, seedlings develop a taproot usually 6-18 inches long. After the first year, lateral root growth tends to be greater than vertical growth. A water table within four feet of the soil surface along with a loose soil encourages early rooting depth. The uptake of soil moisture and mineral nutrients is improved by the formation of symbiotic mycorrhizae on seedling roots.

Most root elongation occurs in the spring and early summer. Root systems typically are moderately deep and wide spreading. Vertical roots (taproot and sinkers) typically descend 5-15 feet. Lateral roots mostly occur within 4-18 inches of the surface, and can extend up to 40 feet beyond the crown (depending on competition from neighboring trees). Root grafts among neighboring red pine trees older than 15 years are common. Thinning apparently stimulates grafting. Grafting among trees can enhance tree health and windfirmness, but can also transmit damaging agents, including annosum. Soil conditions, including moisture, temperature, texture, and density, can influence the

timing, intensity, and pattern of root growth. Root systems become stunted in poorly drained soils and some dense soils (e.g. hardpan and compacted soils).

Red pine trees often grow to 70-80 feet tall, and up to 36 inches dbh. Maximum size is nearly 150 feet tall and 60 inches dbh. Height growth rate is strongly influenced by site quality. Other factors that can impact height growth are overhead shade and damage to terminal growth (e.g. insects). The rate of height growth tends to decrease as trees get older, and often becomes negligible as trees approach 150 years old. Diameter growth rates tend to be the greatest in vigorous, dominant trees with large, well developed crowns. Crown size and diameter growth are strongly influenced by stand density. Basal area growth rates range from <1 to >8 square feet per acre per year, but most commonly range 2-5 ft²/ac/yr. Factors influencing variability in basal area growth include site quality, stand age, and density extremes (<60 and >200 ft²/ac). Greatest growth rates generally are demonstrated by young stands on good sites, and slowest growth rates by old stands on poor sites.

Red pine is a long-lived species. Individual trees can reach 350-400 years of age. Fully stocked stands can persist for at least 200 years, but may exhibit declining tree vigor, increasing mortality rates, and declining stand yield.

MANAGEMENT GOALS AND OBJECTIVES

Stand management objectives should be identified in accordance with landowner property goals, and within a sustainable forest management framework which gives consideration to a variety of goals within the local and regional landscape. The silvicultural systems described herein are designed to maximize tree vigor and stand growth to facilitate optimized productivity (quantity and quality) of a variety of timber products (e.g. sawtimber, pulpwood, utility poles, and cabin logs). These silvicultural systems may be modified to satisfy other management objectives, but vigor, growth, and stem quality could potentially be reduced.

Prior to development and implementation of silvicultural prescriptions, landowner property management goals need to be clearly defined and articulated, management units (stands) must be accurately assessed, and landowner stand management objectives should be detailed. In-depth and accurate stand assessment will facilitate discussion of stand management options and objectives within the context of realistic and sustainable property management goals.

Red pine stand assessment should include quantifying variables such as:
- Present species composition
  - Canopy, shrub, and ground layers
  - Sources of regeneration
  - Potential growth and competition
- Stand structure
  - Size class distribution and density
  - Age class distribution
- Stand and tree quality
- Site quality - The habitat type is the preferred indicator of site potential. Other indicators of site potential include site index, soil characteristics, and topographical characteristics. Site has a strong influence on volume growth and potential yield.
- Stand and site variability

SILVICULTURAL SYSTEM

A silvicultural system is a planned program of vegetation treatment during the entire life of a stand. All silvicultural systems include three basic components: intermediate treatments (tending), harvesting, and regeneration. For red pine stand management, even-age management is recommended.

- Periodic thinnings based on basal area control are recommended.
- Artificial regeneration is the most reliable and most commonly practiced method to regenerate stands. Proper site selection, site preparation, and competition control are important for artificial regeneration to be successful.

MANAGEMENT RECOMMENDATIONS

Planting Density
Chapter 22 provides guidelines for artificial regeneration and includes species specific considerations. Efficient and successful stand establishment is critical to long-term growth and productivity. Sites must be properly prepared before planting to facilitate operations and control competition. When harvesting and replanting red pine, consider waiting two years before replanting to reduce risk of seedling damage from insect infestations. Planting density (spacing) recommendations depend on many factors, including management objectives, silvicultural practices planned, and planting conditions.

Recommended planting densities range from 500-1000 trees per acre (TPA). At least 400 well distributed TPA are required to provide minimum recommended stocking when stands reach poletimber size (≥5 inches dbh); in general, most stands reach the poletimber size class in 15-30 years following planting. Commonly, production oriented planting densities range from 700-900 TPA.
Advantages of higher planting densities (e.g. 750-1000 TPA):
- Partial mortality less likely to result in understocked conditions.
- Increased options for crop tree selection.
- Potential to reduce size and persistence of branches on lower bole.
- Increased cubic foot volume growth rates of young stands.
- Release – less competition from other species (less weeding)

Advantages of lower planting densities (e.g. 500-750 TPA):
- Lower planting costs.
- Increased tree diameter growth rates.
- Longer retention of abundant shrub and herb layers to enhance plant diversity
- Release – less intra-stem pine competition [less cleaning (precommercial thinning)]

When planting, consider including some species diversity to expand future management options and to provide sustainable forestry benefits. Other species can be included through integrated planting (e.g. white pine), planting patches (e.g. white pine, oak), or natural regeneration in patches (e.g. white pine, oak, birch, aspen) (see following section Managing Mixed Stands).

**Seedling/Sapling Stands**

Efficient and successful stand establishment, and maintenance of early growth and productivity have a disproportionate effect (as compared to later intermediate treatments) on timber productivity over the rotation.

Stocking should be maintained between 400 and 1000 well distributed trees per acre. Sapling crop trees may be most productive with ≥50 ft$^2$ of growing space.

If mortality becomes excessive and minimum stocking levels are not maintained, then reinforcement planting will be necessary and should be implemented within the first two years of initial planting. Control competing vegetation, and interplant red or white pine seedlings. If beyond two years in the ground, then site prep and replant.

Once established, red pine seedlings and saplings generally exhibit optimal vigor (growth and health) when exposed to (near) full sunlight. Crop trees that are maintained in free-to-grow conditions have the greatest potential to maximize growth and productivity. When needed (before seedlings become overtopped), release operations are recommended to control competition and maintain tree vigor.

- Cleaning (sometimes termed precommercial thinning) overstocked stands will maintain crown development and diameter growth rates.
- Liberation can reduce shade cast by older, overtopping trees; however, retaining reserve trees of other species is recommended (see Chapter 24).
- Weeding can control undesirable vegetation (e.g. exotic species or competing shrubs and herbs)

**Intermediate Treatments – Thinning**

**Basic Concepts**

Intermediate treatments generally are designed to enhance tree growth, health, and quality, and stand composition, structure, and value. Thinning is a cultural treatment conducted in stands past the sapling stage to reduce stand density. It entails the removal of trees to temporarily reduce stocking to concentrate growth on the more desirable trees. Thinning can impact stand growth, compositional and structural development, and economic yield. It provides the main method, implemented between regeneration and final harvest, to increase the economic productivity of stands. Normal thinning does not significantly alter the gross production of wood volume.
Objectives of thinning include any of the following:

- Enhance the vigorous growth of selected trees through the removal of competitors. Larger diameter, more valuable trees can be grown in a shorter period of time.
- Enhance tree health. Thinning maintains tree vigor and strength, and anticipates losses.
- Harvest most merchantable material produced by the stand during the rotation. Trees that would die from competition are harvested and utilized for timber products.

Application of thinnings can increase economic yields:

- Harvest anticipated losses of merchantable volume.
- Yield of income and control of growing stock during rotation.
- Increased value from rapidly growing larger diameter trees.
- Increased value from improvements in product quality.

A schedule of thinning for a stand should identify the thinning methods to be used, the intensity of application, and when thinnings will occur. Thinning schedules should be systematically and carefully developed, because the effects of these cultural practices will be manifested in future growth and development and will influence future management options.

Stocking charts (Figure 32.9) generally guide density management during intermediate thinning treatments. In managed red pine stands, maintain stocking between the A-line and B-line on the stocking chart. Do not allow stand density to surpass the A-line, and do not reduce stand density to below the B-line. Within this range (between A- and B-lines), trees fully utilize (occupy) the site, and stand growth and merchantable board-foot volume yield are optimized. Thinning can occur at any time and stocking managed at any level as long as stand density is maintained between the A- and B-lines.

Advantages of higher residual thinning densities in red pine stands:

- Increased options for crop tree selection.
- Potential to reduce size and persistence of branches on lower bole.
- Potential to reduce stem taper. Taper is self-correcting over time, as the crown moves upwards and height growth declines.
- Greater flexibility for responding to mortality and pest problems.
- Products – increased yields of smaller diameter products and poles.
- Increased cubic foot volume growth rates of young stands.

Advantages of lower residual thinning densities in red pine stands:

- Increased crown vigor and tree diameter growth rates.
- Concentrates growth on best quality trees.
- Products – increased sawtimber production at younger ages.
- Better development of shrub and herb layers and increased within stand compositional and structural diversity.

The effects of thinnings are temporary. After each thinning, the remaining trees grow taller, diameters increase, crowns expand, and canopy gaps close; stand density increases. Periodic thinnings can maintain crown vigor and accelerated diameter growth rates of crop trees. Factors to consider in determining when to conduct further thinning operations include: stocking, diameter distribution and growth rates, crown development and vigor, timber yields and economics, and landowner goals and stand management objectives.

Thinnings – Timing and Intensity

Refer to stocking chart (Figure 32.9). Maintain stocking between the A-line and B-line. Thinning can occur at any time as long as stand density is maintained between the A- and B-lines. The A-line is not a thinning “trigger.” When to thin depends on management...
objectives, stand conditions, and operability.

Typically, thinning is implemented when basal area stocking is at or above the midpoint between the A- and B-lines, but before stand density reaches the A-line. Reduce stocking to a density near the B-line, choosing a residual basal area that will accommodate landowner objectives. A general rule of thumb is do not remove >50% of the basal area in any one thinning operation.

Overstocked stands (greater than A-line stocking), where thinnings have been delayed, may be comprised of tall, thin, small-crowned trees that are susceptible to wind, snow, and ice damage following heavy thinning. In these stands, to develop tree vigor and strength, thin lightly and frequently, with increasing intensity, for the first several thinnings, until target residual densities are achieved. A general rule of thumb is do not remove >33% of the basal area during the initial thinning.

Standardized thinning regimes (simplified, general guidelines) aim to sustain consistent growth and productivity throughout the rotation, and to produce a variety of timber products from thinnings and final rotational harvest.

- **Poletimber (5-9 inches dbh)**
  - Typically operable when basal area is 100-180 sq. ft. per acre
  - As a general guide, reduce basal area to slightly above the B-line, to 70-110 sq. ft. per acre; 90 sq. ft. per acre can provide a standard target residual basal area.

- **Small sawtimber (10-15 inches dbh)**
  - Typically operable when basal area is 140-200 sq. ft. per acre
  - As a general guide, reduce basal area to slightly above the B-line, to 100-140 sq. ft. per acre; 120 sq. ft. per acre can provide a standard target residual basal area.

- **Large sawtimber (>15 inches dbh)**
  - Typically operable when basal area is 160-220 sq. ft. per acre
  - As a general guide, reduce basal area to slightly above the B-line, to 110-160 sq. ft. per acre; 140 sq. ft. per acre can provide a standard target residual basal area.

Thinnings are usually implemented every 8-12 years in young pole-sized stands and every 10-20 years in older sawtimber stands.

An important consideration when thinning red pine stands is the identification and control of Annosum root rot and red pine pocket mortality. For Annosum root rot, prevention is key. A new infection site primarily originates when spores land on freshly cut stumps; the fungus also spreads through root contact and root grafting. If Annosum is not present in the stand, consider treating freshly cut stumps with a fungicide (e.g. “Sporax,” “Cellu-Treat”) to prevent new infections. If Annosum is present in the stand, follow detailed Forest Health Protection guidelines.

Red pine pocket mortality is apparently caused by a complex of insects and the fungi *Leptographium*. Pockets typically start small with one to a few dead trees surrounded by trees that have reduced shoot growth and thin crowns. Each year, a few trees on the pocket edge may die and the edge of the pocket expands. *Leptographium* spp. move below ground through root contact and the pocket expands about 1 chain every 10 – 15 years. Cut dead trees and trees that are showing dieback and/or yellowing of the foliage within and adjacent to the pocket; consider cutting a buffer area of healthy trees around the pocket. As long as total pocket area is not excessive, pockets can be treated as natural openings to provide habitat diversity. See the following section, Forest Tree Health Management Guidelines for Red Pine, for additional information and references.

**First Thinning – Methods**

At least 400 trees per acre are required to provide minimum recommended stocking when stands reach poletimber size (B-line stocking when average dbh of trees in stand is 5 inches). Most red pine stands reach the poletimber size class in 15-30 years following planting; the first thinning generally occurs at the age of 20-25 years, when the trees are poletimber sized and merchantable products can be harvested.

- **Plantations with Distinct Rows**
  - **Mechanical Row Thinning**
Mechanical row thinning is an efficient method for the first thinning. Every other row or every third row is mechanically removed. The space created within the cut rows should be wide enough to accommodate processors and forwarders. Maintain stocking between the A-line and B-line, as recommended in the preceding discussion of thinning intensity.

- Mechanical Row and Low Thinning

Mechanical row and low thinning methods can be integrated for the first thinning. Every fifth row is mechanically removed, and a low thinning is applied within the remaining rows. The space created within the cut rows should be wide enough to accommodate processors and forwarders. Maintain stocking between the A-line and B-line, as recommended in the preceding discussion of thinning intensity.

In very dense plantations where removal of individual rows will not provide access strips of sufficient width to accommodate equipment (processors and forwarders), then alternatives are:

- Mechanical row thinning, removing two adjacent rows and retaining two adjacent rows.
- Mechanical row thinning and low thinning, removing two adjacent rows and retaining five rows. To achieve target residual basal area stocking, a low thinning is conducted within the retained rows. Maintain stocking between the A-line and B-line, as recommended in the preceding discussion of thinning intensity.

On steep topography with equipment limitations, where rows were planted on the contour, follow guidelines for “Plantations with Indistinct Rows,” running the access strips up and down the slope.

- Plantations with Indistinct Rows and Natural Stands – Mechanical Strip and Low Thinning

In plantations where rows are indistinct and in natural stands, mechanical strip thinning combined with low thinning is recommended. Access strips of sufficient width for mechanized access are systematically designated and cut throughout the stand. Depending on equipment needs and expectations, cut access strips generally are 10-15 feet wide. Typical spacing of cut access strips is every 50-60 feet. To achieve target residual basal area stocking, a low thinning is usually conducted within the leave strips. Maintain stocking between the A-line and B-line, as recommended in the preceding discussion of thinning intensity.

Subsequent Thinnings - Methods

Free thinnings that integrate low and crown thinning techniques are recommended (see Chapters 23 and 24). Follow crop tree selection and order of removal guidelines.

Select crop trees for retention.

**Crop tree selection criteria:**

- Low risk of mortality or failure (main stem breakage)
- Good crown vigor
  - Dominant or codominant trees
  - Good silhouette and healthy needles
  - Good crown/length ratio – live crown ratio >30% will provide best response to thinning
- Good stem quality
- Desirable species

Trees may also be selected for retention to achieve other objectives, such as aesthetics or wildlife management.

Select trees to cut, following the standard order of removal.

**Standard order of removal:**

- High risk of mortality or failure (unless retained as a wildlife tree)
- Release crop trees
- Low (lower) crown vigor
- Poor (poorer) stem form and quality
- Less desirable species
- Improve spacing

Alternatively, thinnings can be either low thinnings or crown thinnings, depending on assessment of tree and stand growth.
and mortality. Low thinnings are most applicable in early thinnings, particularly poletimber stands. Low thinnings mostly remove slower growing and higher risk trees (suppressed, intermediate, and poor codominants); heavy low thinning is recommended in order to provide some release to the crowns of crop trees. Crown thinnings mostly remove lower vigor, poorer quality canopy trees in order to favor (release crowns of) the best trees in the dominant and codominant crown classes.
Reserve Tree Retention
At rotation, when a red pine stand is harvested, retain reserve trees (see Chapter 24).

If red pine will be regenerated, consider disease issues. *Sirococcus* and *Diplodia* can occur when red pine seedlings are establishing under mature red pine. If these diseases are a threat locally, then do not retain red pine reserve trees; do retain reserves of other species if available. Consider creating some species diversity when regenerating the stand to expand future management options.

Managing Mixed Stands
Stands of mixed species composition, but predominantly red pine, can develop through artificial or natural regeneration. Maintaining species diversity within stands provides many potential benefits (compared to managing monocultures), including diverse sustainable forestry benefits (e.g. improved wildlife habitat), increased resilience in response to disturbance (e.g. disease outbreaks), and increased future management options. On sites where red pine most commonly occurs, common associates are white pine, jack pine, oak, aspen, and birch; successional progression tends to be toward white pine and red maple. On richer, more mesic sites, successional progression tends to be toward mesic hardwoods (e.g. maples). Within plantations where red pine is predominant, other species can be included through integrated planting (e.g. white pine), planting patches (e.g. white pine, oak), and natural regeneration in patches (e.g. white pine, oak, birch, aspen).

Mixed pine plantations with red pine predominant will be managed by even-aged systems. Planting design should consider the silvics of each species (e.g. differential growth rates), management objectives, future silvicultural practices (e.g. thinning methods and residual stocking distribution), and planting efficiencies. Species can be planted in single or multiple rows, or in complex mixtures. In most cases, mixed pine stands should be planted at a density of 700-1000 trees per acre, and maintained at this stocking level while in the seedling and sapling stages. Seedlings and saplings should be maintained free-to-grow and released as necessary. Poletimber and sawtimber stands are regularly thinned based on basal area control.

Red Pine – White Pine Mixed Stands
See Chapter 31 for guidelines on white pine management. White pine is potentially somewhat longer-lived than red pine. Recommended rotation ages are similar; red pine can be rotated at younger ages, but potential extended rotations are nearly identical. In mixed red-white pine stands, rotation age can be based on either red pine or white pine guidelines; rotation ages ≥100 years are most suited for mixed stands.

In mixed red-white pine stands, both species can be maintained as vigorous associates throughout the rotation. When thinning, consider:
- Methods: In general, free thinnings will be applied; follow guidelines for crop tree selection and order of removal. Row thinning should only be applied at the first thinning if necessary for access and/or if planned for at planting.
- Timing: Thinnings are usually implemented every 8-12 years in young pole-sized stands and every 10-20 years in older sawtimber stands.
- Intensity: Target residual basal areas can be interpreted from the stocking guides; the following thinning guideline should work well: 90-100 ft²/ac for poletimber, 120-130 ft²/ac for small sawtimber, and 140-150 ft²/ac for large sawtimber.

Red Pine – Jack Pine Mixed Stands
See Chapter 33 for guidelines on jack pine management. Red pine and jack pine are associates, particularly on dry, nutrient poor sites; however, mixed stands may increase the risk of insect damage to red pine (e.g. root tip weevil and jack pine budworm). Jack pine is generally shorter-lived than red pine, and recommended rotation ages are shorter. In some mixed stands, red pine and jack pine will be managed together throughout a relatively short rotation (e.g. 60-70 years); this scenario is most likely when the harvest of jack pine will leave the remaining red pine stand understocked. In most mixed stands, jack pine will be harvested over several thinnings, and stands will become increasingly dominated by red pine. When thinning mixed red and jack pine stands, follow red pine thinning guidelines; the appropriateness of an initial row thinning will depend on access issues and species spatial distributions.
Management of Red Pine Plantations Cultivated Outside of the Natural Range of Red Pine

Red pine reaches its native geographic range limit in southern Wisconsin (Error! Reference source not found. and

Figure 32.5). Most of southern Wisconsin, as well as the central eastern zone and much of the western coulee region harbored only a few red pine community outliers. Apparently, climate, soils, and/or disturbance regimes did not favor the establishment and maintenance of red pine dominated forests.

Plantations have been established in southern Wisconsin, outside of the natural range limits for red pine. Soils typically are dry-mesic to mesic, nutrient rich, and loamy; some soils are calcareous either near the surface or in the subsoil. Long-term growth, productivity, and tree health are uncertain, but observations indicate that red pine is not well adapted to the environment, and that stands often decline at young ages.

Observations of plantation performance typically indicate excellent early growth. However, at comparatively young ages, anywhere between 20 and 60 years old, tree health and mortality problems often develop and stand growth slows or stagnates. In southwestern Wisconsin, red pine plantations often show signs of stress and decline very early, around 20-30 years old, and often by age 40-50 years growth has stagnated and significant mortality can result in understocked stands. Similar patterns of decline have been observed in southeastern Wisconsin, but signs of tree stress and stand decline generally occur in somewhat older stands. Stressed trees lack vigor, crowns may be small and thin, and the tips of branches may appear tufted (lion’s tail); stressed trees may not respond to thinning. In general, many red pine stands do not remain productive (volume/acre/year) until or beyond 60 years of age, and rotation age guidelines developed for red pine in northern and central Wisconsin (within red pine’s native geographic range) do not apply to the management of these stands.
All of the environmental factors causing early decline of red pine stands in southern Wisconsin have not been determined with certainty. Fine textured calcareous soils probably are a major factor. Interactions between climate, insects and diseases, and red pine growth patterns probably also contribute to declines.

Management Recommendations

For established red pine plantations:

- Monitor tree vigor and mortality, and stand growth and productivity
- As long as vigor and productivity are maintained, continue to manage the stand following standard red pine silvicultural guidelines (i.e. intermediate treatments).
- If tree vigor declines significantly, stand-level mortality becomes significant, and/or productivity declines (MAI), then rotate and convert the stand to species more suitable to the site. Early decline is common in red pine plantations cultivated outside of the natural range of red pine in southern Wisconsin.

If considering planting red pine (afforestation or reforestation):

- Evaluate the site and experience with red pine management on similar sites in the area.
- Evaluate the potential to regenerate other species (artificial or natural regeneration) suited to the site and native to the area.
- In general, it is not recommended to establish plantations dominated by red pine outside of the natural geographic range of red pine in Wisconsin.
KEY TO RECOMMENDATIONS

Note: The following recommendations assume the management objective is to maximize tree vigor and stand growth to optimize productivity (quantity and quality) of a variety of timber products.

A. Seedling/Sapling Stands (<5" DBH)

<table>
<thead>
<tr>
<th>1. Fully stocked stands (400-1000 TPA) or overstocked stands</th>
<th>Maintain 400 to 1000 TPA that are vigorous and free-to-grow. When needed, release operations are recommended to control competition and maintain tree vigor.</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Understocked stands (&lt;400 TPA)</td>
<td>Interplanting will be necessary, and should be implemented within the first two years of initial planting. Control competing vegetation, and interplant red or white pine seedlings. If beyond two years in the ground, then site prep and replant.</td>
</tr>
</tbody>
</table>

B. Poletimber and Sawtimber Stands (≥5" DBH)

<table>
<thead>
<tr>
<th>1. Fully stocked stands or overstocked stands</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Understocked stands</td>
<td>5</td>
</tr>
<tr>
<td>2. Poletimber – first thinning</td>
<td>3</td>
</tr>
<tr>
<td>2. Poletimber – previously thinned, or Sawtimber</td>
<td>4</td>
</tr>
<tr>
<td>3. Distinct rows</td>
<td>Review thinning guidelines. Determine if a thinning could be recommended. If a thinning will not be recommended, then determine a date for future reassessment of growth and thinning opportunity. If a thinning will be prescribed, then determine target residual basal area. Follow guidelines for “Mechanical Row Thinning or Mechanical Row and Low Thinning”</td>
</tr>
<tr>
<td>3. Indistinct rows or natural stands</td>
<td>Review thinning guidelines. Determine if a thinning could be recommended. If a thinning will not be recommended, then determine a date for future reassessment of growth and thinning opportunity. If a thinning will be prescribed, then determine target residual basal area. Follow guidelines for “Mechanical Strip and Low Thinning”</td>
</tr>
</tbody>
</table>
### 4. Poletimber – previously thinned

Review thinning guidelines.

Determine if a thinning could be recommended.

If a thinning will not be recommended, then determine a date for future reassessment of growth and thinning opportunity.

If a thinning will be prescribed, then determine target residual basal area.

Apply **crop tree selection** and **standard order of removal** criteria.

### 4. Sawtimber

Review thinning guidelines.

Determine if a thinning could be recommended.

If a thinning will not be recommended, then determine a date for future reassessment of growth and thinning opportunity.

If a thinning will be prescribed, then determine target residual basal area.

Apply **crop tree selection** and **standard order of removal** criteria. If first thinning, consider adaptations for equipment access.

Harvest at rotation age.

### 5. Landowner objectives include red pine management, and the site is suitable for red pine management.

Cut overstory, prepare site, and replant to red pine.

When harvesting and replanting red pine, consider waiting two years before replanting to reduce risk of seedling damage from insect infestations.

### 5. Landowner objectives indicate a preference for other feasible cover types, or the site is not suitable for red pine management.

Convert to another cover type; apply artificial or natural regeneration methods.

If planting to other pine, consider waiting two years before replanting to reduce risk of seedling damage from insect infestations.
ROTATION LENGTH

Rotation Definition
In even-aged silvicultural systems a rotation is defined as the period between regeneration establishment and final cutting. The length of rotation may be based on many criteria, including culmination of mean annual increment (CMAI), target size, attainment of a physical or value growth rate, and biological condition.

Choosing an Appropriate Rotation Age
Selecting when to rotate a stand is based on multiple considerations, including landowner goals, stand condition, and expected future growth. The rotation ages provided are guidelines based on literature, empirical data, and professional experience. In application, foresters will need to regularly review stands in the field and exercise professional judgment concerning tree vigor and mortality, and stand growth and productivity. Different rotation lengths can result in increased production of some benefits and reduced production of others, and landowner goals will help inform the evaluation of the benefits and costs (ecological, economic, social) associated with different forest management strategies. Below are rotation length guidelines based on three different management emphases to accommodate a variety of landowner goals.

Figure 32.4. Economic, biological, and extended rotation length recommendations for red pine.

Economic Rotation (Maximum Net Present Value)
The economic rotation age seeks to maximize the net present value of the stand. It may only include financial (monetary) aspects but could also include non-timber benefits. The inclusion of non-timber benefits may shorten or lengthen the rotation age depending on the non-timber benefits included. Landowners who choose economic rotation ages generally want to maximize the financial performance of the stand. Economic rotations will vary depending on the target discount rate, frequency of thinnings and other factors including estimated costs and revenues. For more details on the factors that affect economic rotation age, please refer to the Economics Chapter (Chapter 62). Another consideration for plantation red pine in Wisconsin is the optimal diameter and an accurate estimate of time required to achieve it. Generally, once a red pine stand has reached its highest value product class, from a financial perspective net present value is often maximized and it is better to harvest since waiting will not add volume fast enough to compensate for the time value of money. For example, at the time this chapter was published, utility pole markets in Wisconsin were generally the highest value product class for red pines. Research on red pine in the Lake States, as well as actual stands modelled in Wisconsin, indicate that current economic rotations for well managed red pine stands are most commonly maximized between 50-70 years (Grossman and Potter-Witter 1991; Lothner and Bradley 1984; Minnesota DNR 2013; Naurois and Buongiorno 1986; Steigerwaldt 2016). Intensively managed plantations on high quality sites may reach economic rotation prior to 50 years, while unmanaged plantations and/or poor-quality sites may have longer economic rotations. Red pine markets can change and new markets, changing mill standards, or supply chain constraints may affect economic rotation ages.

Biological Rotation (Culmination of Mean Annual Increment)
The biological rotation seeks to maximize long-term sustained yield, or volume production. In this guideline, the range in rotation ages is defined at the lower end by the age at which maximization or culmination of mean annual increment (CMAI) growth occurs and at the upper end by the average stand life expectancy. Little objective data exists identifying these endpoints in general and even less by site type. The recommended rotations provided are our best estimates of these endpoints based on the literature and empirical data. The biological rotation range is suitable for a variety of landowner goals. Shorter rotations of 60-90 years tend to maximize cubic foot production, whereas longer rotations of 80-120 years tend to increase board foot production and may accommodate other landowner goals.

Extended Rotation
Extended rotation involves growing stands beyond typical biological rotation ages yet younger than average tree life expectancy, with the objective of managing for both commodity production and the development of some ecological and social benefits associated with older forests. Ecological benefits of extended rotations can include an abundance of large trees, more diverse vertical structure, and greater levels of standing snags and coarse woody debris that support organisms
associated with these structures. Most natural origin stands in Wisconsin fall within this age range and are often managed on extended rotation due to their ecological importance and rarity on the landscape.

**Flexibility in Rotation Length Guidelines**

The recommended rotation ages presented here are appropriate for most stand conditions and landowner goals encountered in plantation and natural origin red pine stands. Foresters may modify these guidelines to accommodate specific stand conditions and management objectives. Modifications to these guidelines should always be scientifically sound. Some of the more common modifications include early rotations due to significant stand health concerns, modifications to regulate a species’ age class distribution at the property/landscape level, and accommodations due to operability challenges. In addition, some intensively managed plantations on high quality sites may reach economic rotation and their highest value product class sooner than expected.

**Red Pine Plantations Cultivated Outside of the Natural Range**

Part of southern Wisconsin is outside of the native geographical range of red pine. On some sites, early growth can be excellent, but stand growth and tree health often decline at relatively young ages. Foresters should monitor tree vigor and mortality; as well as stand growth and productivity on these sites early. As long as vigor and productivity are maintained, continue to manage the stand following standard red pine silvicultural guidelines (i.e. intermediate treatments). If tree vigor declines significantly, stand-level mortality becomes significant, and/or productivity declines (CMAI), then rotate and convert the stand to species more suitable to the site.
MANAGEMENT ALTERNATIVES

Natural Regeneration Methods

Silvicultural methods to regenerate red pine by natural regeneration (seed) are rarely applied. Successful natural regeneration requires a suite of coinciding factors which can be difficult to coordinate. Significant silvicultural considerations that can limit the successful establishment of natural regeneration include: seed production, seedbed conditions, moisture availability during the first two growing seasons, sunlight (shade), and competing vegetation.

Shelterwood and seed tree are potential natural regeneration methods for the red pine type. However, they have been poorly studied, and success has been highly irregular. Significant silvicultural considerations include management of overstory seed sources and shade, timing to coordinate site prep and seed production, and competition control. Drought during seedling establishment can be a limiting factor. Rapid brush invasion has been one of the most important causes of failure of red pine reproduction. In addition, disease problems (i.e. Sirococcus and Diplodia) can occur when red pine seedlings are establishing under mature red pine.

Key Requirements

- **Good Seed Crop**
  - Very irregular, occurring on average every 3-7 years, with bumper crops every 10-12 years
  - Most seed is dispersed within 40’ during September to November
  - Seed germinates spring to early summer
- **Soil Moisture**
  - Moist soil throughout spring and summer is essential to germination, survival, and growth. Seedlings are very susceptible to dessication during the first growing season, and somewhat so during the second season.
- **Site Preparation**
  - Seedbed – bare mineral soil preferred (light pine litter acceptable)
  - Competition control
- **Sunlight and Shade**
  - >80% crown closure limits establishment
  - Approximately 65% crown closure recommended for initial establishment (shade facilitates moisture retention and may limit competition)
  - <60% crown closure provides best seedling growth and development for establishment (if moisture and competition are not limiting)
  - <20% crown closure provides best growth once established
- **Competition Control**
  - To ensure seedling survival and vigor

Shelterwood/Seed Tree Regeneration Methods

- **Seeding cut alternatives**
  - Strip Cut (seed tree/shelterwood hybrid)
    - Cut strips 50’ wide and leave uncut strips 15’-20’ wide (removes 70-80% of the overstory)
  - Shelterwood / Seed Tree
    - Recommended cut: 60% crown closure to provide seed and shading
    - Minimum cut: retain up to 70% crown closure
    - Maximum cut: retain 20-30 trees per acre to provide adequate seed coverage with a good seed crop
  - Seed trees retained are desirable species of good vigor and quality
  - Scattered seed trees and strips may be susceptible to windthrow on some sites
- **Final overstory removal cut**
  - When a well stocked stand of desirable, vigorous seedlings is well established, ideally in 3-8 years
    - Well stocked is >500 well distributed seedlings/acre remaining following overstory removal. Stocking requirements prior to overstory removal will depend on overstory density and distribution, and logging methods.
    - Well established is 2-4 feet tall
Remove overstory to ≤15% crown closure to optimize growth of seedlings and saplings.
- Retention of reserve trees is recommended
- In general, red pine should not be retained as a reserve tree (over red pine regeneration), because of potential disease incidence (i.e. *Sirococcus* and *Diplodia*)

**Recommended Natural Regeneration Process**

- Overstory seeding cut, either:
  - Shelterwood cut to 60% crown closure
  - Strip cut
- Wait two or more years for crown development and understory development (sprouts and germinants of competitors)
- Monitor potential red pine seed crops
- Implement site preparation (prepare seedbed and control competition) during late summer before a good or better seed crop
- Monitor regeneration and release as needed to control competing vegetation
- Overstory removal cut
- Release as needed

**Overstory Removal**

In red pine stands, conditions required to implement overstory removal rarely develop. Overstory removal is an even-aged natural regeneration method implemented in stands at rotation age that removes all trees in one cut to fully release desirable advance regeneration that is well stocked and well established.

- Well stocked is >500 well distributed vigorous seedlings/acre remaining following overstory removal.
- 1000-3000 seedlings/acre prior to logging would facilitate maintenance of adequate stocking following logging damage.
- Logging damage to regeneration should be minimized to the extent feasible.
- Well established is 2-4 feet tall.

Retention of reserve trees is recommended. In general, red pine should not be retained as a reserve tree (over red pine regeneration), because of potential disease incidence (i.e. *Sirococcus* and *Diplodia*)

Following overstory removal, release may be needed in 1-10 years to maintain seedlings and saplings free-to grow and vigorous.

**Prescribed Fire**

Prescribed surface fire in mature red pine stands can be an effective management tool for eliminating shrub competition, reducing thick duff layers, and preparing mineral seedbeds. Young stands of red pine 1-49 years, are susceptible to damage and mortality, however, once the tree reaches 60 feet tall (roughly 50 yrs old), the bark is thick enough to protect the cambium and crown from extreme fire damage (Rouse 1988). Burning is a less expensive alternative to other site preparation techniques, however, due to the risk and related liability issues it may not always be the best method. Depending on the type and intensity of the burn, some very intense burns may cause some damage to the tree and affect its merchantability. Burning, soon after timber harvest with available slash fuel, can be an effective tool to reduce competition from undesirable trees and shrubs. Growing season fires, conducted repeatedly over several (2-4 years) growing seasons, have been effective at controlling dense shrub (hazel) competition and exposing mineral soil (Buckman 1964). The reduction in hazard abundance in stands receiving several growing season burns can last many decades. Burning can also be an effective at exposing the mineral soil and nutrient availability for an adequate seedbed. Slow burning, cool fires can reduce slash and needle duff, expose soil providing better seedbed conditions for germination.
**Pruning**

Pruning is a silvicultural practice that can be applied to improve log quality and value; it is implemented to promote the growth of clear, knot free wood on the first log. It is a relatively labor intensive and costly practice, implemented in young stands, and economic returns are not realized until (near) the end of the rotation. The financial efficacy of pruning is questionable.

Knots are created by branches and can degrade log quality. Factors related to log quality and branching include the number of branches, the size of branches, and the persistence of dead branches. In red pine, the size and persistence of branches is somewhat influenced by stand density.

In dense stands, red pine self prunes comparatively well. In open stands, trees retain lower branches longer, branches grow larger in diameter, and dead branches persist longer. Pruning can be applied to improve log quality, particularly in stands that are managed at lower density to accelerate diameter growth rates. Combining pruning and aggressive thinning can facilitate the production of increased value in a shorter period of time.

If pruning red pine trees, prune only 50-150 potential crop trees per acre, and only on good to excellent sites. Generally, trees are pruned to 17 feet (the first log) in 2-3 pruning operations. Often, the first pruning is to 9 feet when trees are 18-20 feet tall. Always maintain a crown/stem ratio of at least 50% (at least 50% of total height occupied by crown).

Chapter 23 provides further guidance on pruning.
MANAGEMENT CONSIDERATIONS

Maintaining Soil Productivity

Red pine occurs on a relatively wide range of soil types, with textures that include sand, loamy sand, and sandy loam. In some cases red pine has been planted on heavier soils, including loams and clays. Because red pine typically grows on sandy sites, soil compaction is less of a management concern than in most other forest types. Soil displacement on roads and skid trails can be a concern in red pine stands, particularly for the sandiest sites. When the mat of ground vegetation is removed or worn away, bare mineral soil is exposed and new vegetation is often slow to establish. Erosion by wind and water can keep these areas open, and bank slumping can prevent roadcuts from stabilizing; these impacts make parts of the stand non-productive. Roads and other travel routes have been implicated in the spread of non-native invasive plants. They can also act as barriers to the movement of some species, create habitat fragmentation and edge, and attract continuing human disturbances that prevent revegetation. Use travel routes and landing areas designed to meet the needs of the harvest while minimizing the portion of the stand impacted, and maintain the ground vegetation mat wherever possible. As a general rule, less than 15 percent of a harvest area should be devoted to haul roads, skid trails, and landings (WDNR 2003).

Another area of concern for red pine sites is the potential for nutrient depletion over repeated rotations. Sites accrue nutrients through mineral weathering and atmospheric deposition. Nutrients can be lost from a site through leaching, volatilization (in the case of nitrogen), and removals in harvested wood. If losses are greater than inputs over the course of a rotation, nutrient depletion occurs. If losses are relatively small and the site is “rich”, or has a large amount of nutrient capital, then concerns are minimal. However, if the site is sandy and has little nutrient capital, losses may be significant. There is uncertainty in predicting the exact amount of potential nutrient losses, and more research is needed in this area.

(Perala and Alban, 1982)
Tree species vary in the amount of nutrients they take up, and a large proportion of nutrients are held in the small branches, twigs, and foliage. Perala and Alban (1982) studied nutrient removals in red pine for two sites at Pike Bay, MN (Table 32.4). These red pine plantations were on two different soil types. One soil was a Warba very fine sandy loam with sandy clay loam at a 24 inch depth, and calcareous at 41 inches. The other was an unnamed soil, dominantly loamy fine sand with clay loam and sandy clay loam between 33 and 43 inches, underlain by sand. The red pine stands were 39 and 41 years old, respectively. Compared with other tree species in this study, red pine had a lower nutrient demand than trembling aspen and white spruce, but a higher nutrient demand than jack pine. Nutrient uptake was greater on the richer site.

Potassium (K) appears to be a mineral nutrient of concern for red pine. Nutrient balances for a rotation can be estimated by subtracting harvest removals from atmospheric and mineral weathering inputs. An estimate of the amount of K inputs from atmospheric deposition on average sites is 0.36 lbs/acre/year, based on data from the five Wisconsin stations of the National Atmospheric Deposition Program (NADP), for the time period 1997-2006. Mineral weathering inputs of K on average sites are estimated at 1.5 lbs/acre/year, and on nutrient-poor sites at 0.7 lbs/acre/year (Kolka et al., 1996).

Estimates of biomass and K removals for thinnings and final harvest of a 120-year old plantation are shown in Table 32.5. Inputs over 120 years are estimated to total 223 lbs K per acre on average sites, and 127 lbs K per acre on nutrient-poor sites. Removals of bole and bark wood, with 5% green tree retention at final harvest, represent 139 lbs K per acre. In this case, given uncertainty in the estimates, inputs of K over the rotation are approximately equal to harvest removals on nutrient-poor sites. However, if 80% of foliage and branches were also removed at each thinning, with 5% green tree retention at final harvest, another 243 lbs K per acre would be removed for a net loss of 254 lbs K per acre on nutrient-poor sites. Nutrient capital data for K in Wisconsin soils is not readily available, but figures have been reported for similar soils in adjacent states. The K capital of an average Minnesota soil, to a depth of 40 inches, is around 908 lbs/acre (Grigal 2004). Measurements of K capital for 24 Michigan sites showed values ranging from 106 to 1247 lbs/acre, with averages of 120 lbs/acre for a group of outwash sands, 338 lbs/acre for outwash sands with loamy inclusions, and 810 lbs/acre for loamy glacial till soils (Padley 1989).

This analysis indicates that if red pine foliage and branches are removed from the sandiest sites at thinnings and final harvest, K could be depleted before the end of the first rotation. On outwash sands with loamy inclusions, which are typical red pine sites, K depletion could occur during the second rotation. These calculations are estimates based on limited data, but indicate that caution is warranted in nutrient management of red pine sites.

Table 32.5. Biomass of red pine plantation thinnings and final harvest, and estimated potassium (K) in harvested trees. Plantation yield data are from Bassett (1984), biomass equations are from Ter-Mikaelian and Korzukhin (1997), and K concentration data are from Perala and Alban (1982).
Wildlife Management Considerations

Red pine provides habitat and shelter for wildlife. Young stands are used primarily for shelter. Older stands with closed canopies provide thermal cover. Seeds of red pine can be an important food source for some mammals and birds. Because red pine is a long-lived tree it can serve as a legacy during either natural or artificial stand regeneration. Individual trees or small groups can be important to many wildlife species as nesting platforms or as cavity producers.

Red pine generally grows with associates in natural stands. Wildlife species will benefit from management practices that attempt to simulate natural conditions. Management of natural stands of red pine should recognize the contribution to wildlife of the associated species while maintaining vigor and health of the red pine in the stand.

Plantation management of red pine has often been conducted on open sites and the resulting stands have been relatively simple. Encouraging the development of structural complexity in red pine plantations will benefit wildlife. The presence of ground and shrub layer vegetation in red pine stands in central Wisconsin increased the use of this habitat type by deer, ruffed grouse, and songbirds. Both vertical and horizontal structure can be increased during planting and subsequent treatments. Variable density thinnings with gap establishment will encourage recruitment of multiple layers of vegetation within the plantation. Retention of individuals or small clumps of mature red pine at the time of stand regeneration will increase the value of the plantation to wildlife species; however, disease problems (i.e. *Sirococcus* and *Diplodia*) can occur when red pine seedlings are establishing under mature red pine.

Tree species diversity within red pine plantations is desirable for wildlife. This species diversity can be planned during plantation establishment or encouraged during subsequent thinnings. A mix of species including hardwoods can be planted at the time of stand establishment. In many cases, other species of trees or shrubs can be allowed to remain after establishment of a new stand. Regardless of the source, favoring mast producing shrubs and trees will have the highest value to wildlife dependent on this food source.

Recommendations:

- **Increase compositional (species) diversity within stands**
  - When establishing plantations include a component of other species either directly or through allowing tree species already present to remain.
    - New plantations should have some areas of different vegetation, either openings allowed to regenerate naturally or intentionally planted clumps of different appropriate species.
    - Large plantations should maximize the amount of interface between the plantation and other vegetation types.
  - During intermediate treatments, maintain species diversity. In homogeneous plantations, consider creating some gaps or patches to recruit natural regeneration of other species. Variable density thinning can facilitate the variable recruitment of understory species.

- **Increase structural diversity within stands**
  - Develop and maintain large trees, cavity trees, snags, and coarse woody debris
    - Retain both living and dead legacies during stand rotations.
    - Retain wildlife trees during intermediate treatments.
  - Employ variable density thinning to establish structural complexity within planted stands.

- **Manage some stands on extended rotations to develop both stand and landscape compositional and structural diversity.**

- **Develop and successfully apply methods to naturally regenerate red pine, either in natural stands or in plantations nearing rotation age.**
Endangered, Threatened and Special Concern Species Considerations

Several uncommon species are associated with pine and mixed pine forests (e.g. see northern dry-mesic forest community in the Wisconsin Wildlife Action Plan (dnr.wi.gov/org/land/er/wwap/). Maintaining a conifer component in the landscape is important for biodiversity. However, pine plantations are ecologically deficient in numerous ways compared to native forest communities.

The most important rare species-related consideration for this type is whether or not to establish or re-establish a plantation on a given site. Planting pine will reduce or eliminate habitat, at least temporarily, for the vast majority of the species comprising Wisconsin’s biological diversity, as few species utilize plantation habitats compared to other forest types. Therefore, consideration should be given to biological hotspots, rare community types such as prairie/barrens remnants, and other ecologically important areas when locating and designing plantations. In general, barrens and prairie communities should be avoided whenever possible when establishing plantations, as there are numerous rare species associated with these types (see “Landscape Considerations” for more information regarding plantation siting). Where plantations already exist, there are some techniques can increase community diversity and improve habitat for certain species.

In both natural and planted stands, various stand and landscape-level considerations are important for maintaining habitat for rare species. The “Landscape Considerations” and the “Wildlife Management Considerations” sections outline numerous opportunities to enhance forest diversity and improve species habitat; these include retaining structural legacies, improving forest structural and species diversity, using fire as a management tool, managing for patches of older forest, and considering the stand in the broader landscape context. In addition, rare species can sometimes be accommodated by protecting special habitats such as cliffs, rockslides, prairie/savanna openings, and vernal features.

Considering a broad suite of ecological factors for a site, including its relationship to the surrounding landscape, can enrich the overall forest for many species and improve their chances for survival. In certain cases, however, managers may need to consider accommodating a single rare species known from an area. For example, certain rare plants associated with barrens and prairie habitats may be found in areas where plantations have already been established. By providing adequate sunlight, and avoiding herbicide or other treatments that might eliminate these plants, these species can be accommodated, at least for the short term. The table at the end of this section provides some examples, but other sources should be referenced. Usually modifications designed to accommodate a species can be designed to achieve multiple benefits.

Rare animals occupying red pine forest are mostly found in young (1 to 10 years) and older (> 50 years) forests. Pine-dominated forests in the oldest age classes are currently lacking across most of the state. Rare plants associated with red pine are generally found in stands of natural origin with certain characteristics. Special consideration related to the amount of shade, soil disturbance, and use of herbicides may be needed to maintain habitat for these plants.

A. Structural Retention at the Time of Regeneration Harvest

Retaining structural features from the original red pine stand, such as large vigorous trees, cavity trees, snags, and coarse woody debris can enhance structural complexity. Structural retention is modeled on the biological legacies that remained after natural forest disturbances. Even under the most intense historical fires many individual trees and groves survived. Consider retaining reserve trees and snags in even aged prescriptions to provide habitat.

Little quantifiable data exists on how much structure to retain. Developing standard prescriptions would require thorough analyses of species specific requirements and response to various treatments. In general, retention of old trees can provide benefits such as distinctive architecture with large branches that are used as movement corridors or the foundation for large nests, cavities (both present and future), diverse habitats for insects and spiders which provide the prey base for vertebrates, and maintenance of diverse fine root and fungi systems in the soil.

B. Identify Special Habitats

Many rare species are limited in their distribution to microhabitats within larger blocks of forest. Habitats such as cliffs,
Vernal or ephemeral pools, seeps or springs, rock outcrops, or prairie/savanna remnants may harbor rare species. As only a portion of Wisconsin’s rare species populations have been documented to date, management of these habitats is important to allow undocumented species to persist or for future species to colonize these areas. Often special habitats can be protected while achieving other silvicultural goals such as the retention of biological legacies (see Chapter 24 for more information).

Cliffs may require one of two different approaches, depending on their physical characteristics and the species present. For moist cliffs, sometimes exhibiting seepage flow, modify harvests near the feature to maintain shading and moisture for species requiring those characteristics. For dry cliffs with species requiring more open conditions the removal of shade, especially by removing trees from the base of the cliff, may greatly improve microhabitats.

Vernal Features such as Ephemeral Ponds are uncommon on the sandy sites where natural red pine stands are typically found. Shade should be retained on pools found within forests, – e.g., see the Northern Hardwoods chapter for a discussion. In many cases, pine plantations have been established on former prairie/barrens sites that were regularly affected by fire such as those found in the Northwest Sands. In these areas, there may be benefits to greatly reducing shade around vernal pools, as they may contain species adapted to more open conditions.

Biological Hotspots such as bird rookeries, bat hibernacula, herptile hibernacula, and migratory bird concentration areas can harbor many rare species. These hotspots can be permanent as with hibernacula, or ephemeral in the case of rookeries. Different strategies may apply, depending on the situation. In any situation when these hotspots are encountered, consultation and advice from wildlife or endangered resources specialists should be sought.

Historically, natural and anthropogenic fires occurred across Wisconsin’s landscapes for at least a few thousand years. Fire disturbance of low to moderate intensity and frequency was key to maintaining the northern dry-mesic forest type in the past. Prescribed Fire may reduce competition from broadleaf trees and shrubs while improving habitat for other plant species associated with these forests. These species populations can be greatly enhanced by use of fire, often in combination with understory removal.

Adaptive management is important, because many aspects of endangered and threatened species management are not precisely known, and managers need to rely on the best available information for species life history or ecological disturbance patterns. Information on rare species’ responses to silvicultural techniques in working forests is notably lacking. Documenting the different approaches used by foresters across the state can benefit other managers and biologists and to help to better inform conservation efforts in the future.

Table 32.6. Select rare species that can be associated with red pine stands, their general habitat preferences, and sample management considerations for which they may benefit. These are meant as broad considerations for planning purposes, rather than avoidance measures; please consult additional sources for life history information. The species list is not meant to be exhaustive.

Other rare species may occur in red pine stands. Many of these species will be found in specialized habitats such as rock outcrops, cliffs, ephemeral ponds, prairie / savanna openings, and seeps. If a rare species is known to be present in an area, including Element Occurrences from the NHI Database, refer to the department screening guidance for avoidance and contact the appropriate staff, as needed. Information for NHI Working List species and their habitats can be found through the Bureau of Endangered Resources Web pages (*dnr.wi.gov/org/land/e*).
**Landscape Considerations**

The red pine forest type provides significant economic and social benefits, but there are concerns about the ecological effects of red pine plantation management at landscape and regional scales. Past management has led to altered ecological complexity through development of single cohort, monotypic stands; decrease in older age classes; lack of within stand structural variability; interruption of natural processes; and placement on the landscape, fragmenting other systems. Landscape considerations for red pine are intended to address some of the ecological effects by recognizing management strategies that can be incorporated into management plans and prescriptions.

**Historic Context**

When the General Land Office (GLO) Public Lands Surveys (PLS) were conducted in Wisconsin (1832-1866), forests of white and red pine comprised about 2 million acres (Frelich, 1995); this represented about 9% of forest vegetation, making white pine – red pine the third most abundant forest type. Species composition and successional stage varied depending on soil type and disturbance regime. Red pine was historically a component of the northern dry forest, present along with white and jack pine, and northern dry mesic forest, existing with white pine, red maple, red oak, birch and aspen (Curtis, 1959). The most extensive blocks of white pine – red pine dominated forest were in Vilas and Oneida counties (WDNR 1995).

Figure 32.5 displays red pine occurrence from the PLS; red pine forests were most abundant in the sandy landscapes of northwest, northeentral, northeast and central sands areas of the state. Within the Great Lakes region both Michigan and Minnesota contained considerably more pine forests than Wisconsin (Frelch 1995).

Red pine dominated forests mostly occurred within dry, sandy landscapes where fire was the principle disturbance agent; severe blowdowns occurred infrequently. Severe fires causing mortality of most overstory trees and initiating red pine stand development typically occurred every 100-250 years (return interval); both old and young stands could be decimated by catastrophic fires. As stand development progressed, highly irregular (frequency, severity, pattern) periodic surface fires altered understory composition and structure, and sometimes caused mortality of scattered individuals or groups/patches of
overstory trees. Older trees often were well represented as patches, groups, and individuals. Age class structure within forest
patches ranged from mostly even-aged to complex uneven-aged distributions.

Large pines were especially sought after early in the Euro-settlement period. By the late 1800s, the red and white pine forests
were being removed at the rate of 3.4 billion board feet per year. (Curtis 1959). The pine slash burned easily and intense fires
spread over large areas for several decades until the fire suppression program was developed. Much of the pine forest
converted to aspen-birch and oak following the Cutover (WDNR 2005) or eventually was planted.
Figure 32.5. Map of red pine distribution from the GLO PLS data. A general range line for red pine in Wisconsin in the mid-1800’s has been estimated and inserted to delimit the common occurrence of red pine; community outliers did sporadically occur beyond these range limits.

Current
Red pine is a common cover type, occurring on 4% of forest land in Wisconsin. Most stands are 1-60 years old and of plantation origin. Some of Wisconsin's existing red pine resource was planted on areas devoid of trees, often tax reverted agricultural land, during the 1930s by the Civilian Conservation Corps. On dry sites, where red pine is often cultivated, stands of jack pine, aspen, and oak are sometimes harvested and converted to red pine. The FIA records show that the red pine covertype has been increasing while jack pine has been decreasing since 1983 (Figure 32.6). Between 1983 and 2006 red pine acreage increased from 478,200 acres to 686,167 acres, an increase of 207,967 acres. However, jack pine acres have decreased about 191,000 acres during the same period. Management decisions to convert some jack pine stands to red pine were because of insect/disease issues, particularly jack pine budworm infestations. In some cases, jack pine stands have converted to oak or aspen. On richer, dry-mesic to mesic sites, mixed hardwood stands (e.g. oak, maple) are sometimes converted to red pine plantations. Currently, red pine is often planted as part of afforestation projects to reestablish trees on fallow agricultural lands.
Silviculture Handbook

Figure 32.6. Acreage of red pine and jack pine over 3 FIA inventory periods, 1983-2006.

Most stands of red pine in Wisconsin are 1-60 year old even-aged plantations (Figure 32.7). Some older stands from 80-100 years old also occur. Although red pine is a long-lived native species, there are few current stands that are older than 100 years. Older trees and stands provide unique ecological and social benefits, but are poorly represented within modern forest landscapes.

Figure 32.7. Forest age-class distribution for the red pine forest type in Wisconsin, over 3 FIA inventory periods, 1983-2006.

Table 32.7 shows the distribution of red pine acreage by ecological landscape (EL) and stand origin (plantation or natural) based on FIA data from 2007 and
Figure 32.8 displays a map of natural and plantation red pine in Wisconsin. Of the 697,000 acres of red pine, there were 143,000 acres that were apparently natural stands, and the vast majority, 554,000 acres, were plantations. Of the 14 ELs listed in the table, the Northwest Sands had the largest acreage of red pine forests. Eight ELs contained significant red pine acreage. Nearly half of the natural origin red pine acres occurred in two ELs – the Northwest Sands and the Northern Highland.

Natural stands of red pine are uncommon. Severely altered fire regimes and stand developmental processes have forestalled natural regeneration processes. Historically, fire severity, timing, and pattern significantly influenced red pine regeneration processes across landscapes. Reductions in the frequency, extent, and variability of ground fires have been shown to change dominant successional pathways (Frellich and Reich 1995), influencing understory compositional and structural development.

A few old-growth patches are extant, and there are several relict stands that show no evidence of past harvest. Where found, these are small, and typically mixed with white pine and various hardwoods. Many of these also have not experienced fire for over a century, thus understory composition is increasingly dominated by hardwoods and shrubs rather than natural red and white pine regeneration.
Forest simplification
Forest simplification refers to a reduction of species diversity and structural diversity. Human disturbances (e.g. fire suppression, fire ignition, tree cutting, artificial regeneration, and land conversion) have simplified the composition and structure of red pine forests and altered processes compared to historic conditions (Palik and Zasada, 2003). Management systems that manipulate vegetation and natural processes to encourage natural regeneration are rarely applied. Practices that cause simplification in red pine forests include:

- Application of standardized, homogenized management regimes (disturbance practices), including planting, thinning, and even-aged rotations
- Maintenance of single species, single cohort (even-aged) plantations
- Maintenance of relatively young stands lacking complex structural development
- Harvest of most older and old-growth stands
- Fire suppression

Landscape pattern
Wisconsin’s forested landscapes are made up of patches of different land uses, forest types, and age classes. The relative abundance and spatial arrangement of different patches forms a “landscape pattern” that can affect species’ productivity, metapopulation dynamics, and ecological processes. A landscape made up of natural forest cover often has fewer and larger patches, with subtle and gradual transitional areas between them. Management for red pine can alter this pattern, creating patches of contrasting composition and structure that are typically smaller with abrupt boundaries. This change in landscape pattern breaks up a block of contiguous forest habitat and negatively affects landscape connectivity. Species that are area-
sensitive (more likely to thrive in larger forest patches) or disturbance-sensitive may not find suitable habitat in a landscape that contains multiple blocks of red pine, particularly if rotations are short. Plant and animal dispersal mechanisms can be affected if species or their propagules have difficulty crossing or circumventing the red pine block, cannot find suitable habitat within it, or do not compete successfully with species that may be attracted to red pine or to the disturbance associated with an even-aged rotation.

**Incorporating ecological complexity into red pine management**

Ecological complexity in forest stands refers to compositional, structural, and functional variability across space and time. Variability can be interpreted at different scales; the range of natural variability can provide a realistic benchmark.

Prior to EuroAmerican settlement, variable natural processes guided the development of red pine forests, and resulted in a range of conditions from relatively simple, homogeneous stands to very complex compositional and structural patterns. Currently, managed red pine stands by comparison tend to be relatively homogeneous and simplified. To increase diversity within and among red pine stands, management techniques need to be variable. Management practices and ecological conditions that could enable increased ecological complexity and benefits include:

- Develop and maintain large trees, cavity trees, snags, and coarse woody debris to provide structural diversity and habitat. These structures can be developed in current stands and can provide biological legacies at stand rotation (see Chapter 24). Retention of patches (aggregate retention) can provide unique structure.

- Improve species diversity. Create and manage some gaps within the stand during intermediate treatments and at rotation/regeneration; gaps can be managed using artificial regeneration, natural regeneration, or maintained as openings. Retain other species during intermediate treatments. Retain other species at rotation, especially white pine, to serve as seed sources. When establishing plantations, include other species.

- Apply variable density thinning (VDT). In traditional red pine prescriptions, stands are thinned uniformly. In contrast, most unmanaged forests have varying stand density and size. To emulate the natural variation, foresters can apply different thinning regimes throughout the stand, i.e. some areas heavily thinned and some lightly thinned (Franklin, et al. 2007).

- Reintroduce fire. Ground fires can influence understory composition and structure, and stand successional and developmental processes. Prescribed surface fire in older (>50 years old) red pine stands can be an effective management tool for eliminating shrub and hardwood competition, reducing thick duff layers, and preparing mineral seedbeds.

- Apply natural regeneration practices (see previous section on natural regeneration under Management Alternatives).

- Develop and maintain older forests across landscapes. Extended rotations offer the opportunity to produce significant timber yields while also producing other social and ecological benefits. Managed old-growth focuses on unique ecological benefits. Maintain old-growth and relict stands; they are very rare.
Summary of Landscape Considerations
When deciding whether to actively manage for red pine, assuming the Habitat Type is suitable, consider the following factors:

- Evaluate landscape composition and structure, including species composition; successional and developmental stage; age structure; stand/patch size; type, intensity, and pattern of fragmentation; habitat diversity; NTMB populations and habitat needs; and common/uncommon management techniques.
- Apply landscape scale management by recognizing appropriate placement/location of red pine species in the landscape and the variety, age and size of stands.
- Match stand boundaries with large-scale, enduring physiographic and edaphic features not the present age structure or species.
- Encourage connectivity of forest patches where it is possible to coalesce adjacent red pine stands.
- Promote species diversity within stands during planting, intermediate treatments, and rotation.
- Maintain reserve trees and increase structural diversity within stands through the development and maintenance of supercanopy trees, large trees, large cavity trees, large snags, and coarse woody debris.
- Increase structural diversity within stands through variable density management. Consider the development of gaps and patches of different ages and composition.
- Apply extended rotation and managed old-growth techniques.
- Protect old-growth and relict stands.
- Apply natural regeneration methods and prescribed fire.

Figure 32.9. Stocking Chart for Red Pine (Benzie 1977).

Stocking chart for red pine, displaying the relationship between basal area, number of trees, and mean stand diameter. The area between the A-line and B-line indicates the range of stocking where trees can fully occupy and utilize the site (fully stocked stand).

The stocking chart provides a statistical approach to guide stand density management (see Chapter 23).
- To utilize the stocking guide, statistically accurate estimates of at least two stand variables must be obtained, including basal area per acre, number of trees per acre, and/or mean stand diameter.
The area between the A-line and B-line indicates the range of stocking where optimum stand growth and volume yield can be maintained.
- The A-line represents maximum stocking. Maintaining stocking levels near (but below) the A-line will produce comparatively more trees, but of smaller diameter.
- The B-line represents minimum stocking. Maintaining stocking levels near (but above) the B-line will produce larger diameter trees faster, but comparatively fewer trees.

When designing and implementing a thinning regime for a stand, do not reduce stand density to below the B-line or allow it to surpass the A-line.

Thinning can occur at any time as long as stand density is maintained between the A-line and B-line. The A-line is not a thinning “trigger.” When to thin depends on management objectives, stand conditions, and feasibility.

Typically, thinning is implemented when average stand stocking is halfway or more between the B-line and A-line. Stocking is reduced to near but above the B-line. A general rule of thumb is do not remove >50% of the basal area in any one thinning operation. Crop tree concepts are applied to retain and focus growth on desirable trees, and order of removal concepts are applied to select which trees will be cut to achieve stand management objectives. In overstocked stands, thin lightly and frequently, with increasing intensity, for the first several thinnings, to safely develop tree crown vigor and stem strength, and until target residual densities (near the B-line) are achieved.

| Saratoga Spittlebug - *Aphrophora saratogensis* | - Avoid planting red pine in frost pockets, swales, and any other low lying areas.  
- Remove alternate hosts of Saratoga spittlebug (sweet fern, young willow, berry bushes, etc.) when they occupy 20% or more of the ground cover.  
- Monitor for Saratoga spittlebug populations and treat with insecticides if necessary.  
| **SHOOT DISEASES/CANKERS**                    |                                                                  |             |
| Diplodia Shoot Blight - *Diplodia pinea*      | - Maintain tree vigor.  
- Do not prune trees during wet periods.  
- Avoid two-story or uneven-aged stands in areas with a history of serious *Diplodia* infection.  
- Remove infected overstory and windbreak pines.  
- Avoid planting red pine on dry sites or sites that have a history of serious *Diplodia* infection.

| Sirococcus Shoot Blight (Red pine shoot blight) -  
Sirococcus conigenus (see FHP Figure 1 for the county distribution of this disease)  
Current year’s shoots droop or become stunted and die. The fungus causes shoot dieback and stem and branch cankers on the current year’s growth. A single year of infection could kill seedlings and repeated infections could kill saplings. Understory red pine near older diseased red pine or windbreak pines are likely to be infected by falling spores. | • Do not prune trees during wet periods.  
• Avoid two-story or uneven-aged stands in areas with a history of serious *Sirococcus* infection.  
| Scleroderris Canker -  
*Gremmeniella abietina* (see FHP Figure 1 for the county distribution of this disease)  
Infected needles turn orange at the base in spring and later turn brown and fall off. The fungus moves to branches and main stems to develop a canker. Cankers girdle and kill seedlings and small trees. Damage is minor on trees over 6 feet tall. Lower branch mortality of larger trees occurs in frost pockets. | • Within hazard zone, avoid planting red pine and jack pine in frost pockets, areas of depressed ground where frost conditions are greater earlier and later in the season.  
• Remove all infected red and jack pine. | • How to Identify Scleroderris Canker.  
| **Canker Rot Disease**                       |                                                                  |              |
| Red Ring Rot -  *Phellinus pini*             | • Remove infected trees during thinning.  
• Minimize injuries during logging operations. | • Canker-rot fungi and cankers of Northern Hardwoods.  2004.

</table>
| Pine Engraver Beetle (Bark Beetles) - *Ips spp.* | • Use the pine species and spacing intervals best suited to the site.  
• Thin stands to maintain vigorous and healthy growing conditions - Thin between September and March, if practical.  
If thinning during the growing season, remove harvested timber from the stand within 3 weeks of cutting. Utilize tops down to a 2” diameter.  
Leave branches attached to stem wood to speed drying.  
• Avoid overstocked and overmature stands.  
• Promptly salvage or destroy potential breeding material, such as pines that are severely damaged by wind, lightning, fire, disease, insects, or other destructive agents.  
• If trees have low vigor due to drought, defoliation, or disease, consider a pre-salvage harvest.  
• Harvest newly infested and adjacent trees before the following spring to reduce local populations.  
• Utilize as much of each harvested tree as possible.  
• Minimize logging damage to residual trees. | • Pine Bark Beetles in Wisconsin.  
2007. Wisconsin DNR. Division of Forestry.  
• Bark Beetle Pest Alert: Southern Pine Engraver (*Ips grandicollis*) M. Guthmiller.  
2003. Wisconsin DNR. Division of Forestry.  
• How to identify and manage pine bark beetles.  
2000. Minnesota DNR. Division of Forestry. |

| Red Turpentine Beetle (Bark Beetles) - *Dendroctonus valens* | • Remove weakened or damaged trees from stands.  
• If practical, remove or debark stumps after thinning (rarely practical). | • See Red Pine Pocket Mortality below. |

Tunneling in inner bark causes mortality in sapling to sawlog sized trees, singly or in pockets. Weakened or storm-damaged trees, trees that have been struck by lightning, and overmature or overstocked stands provide a breeding ground for the beetles. Mortality is usually limited to a few trees during years of normal rainfall. However, during dry summers with suitable breeding material, beetle populations quickly build up and cause large scale mortality.

Tunneling under bark causes mortality in weakened trees of pole size and larger. Adult beetles attack dead or weak trees as well as fresh stumps, freshly cut logs, and exposed damaged roots. Although infestation by this insect itself is usually not serious, it vectors *Leptographium* spp. (see Red Pine Pocket Mortality)

</table>
| **Northern Pine Weevil - *Pissodes approximatus*** | • Delay planting seedlings for 2 years after harvesting pines.  
• Remove freshly cut pine stumps before planting seedlings, if practical (rarely practical).  
• Treat freshly cut stumps with an insecticide if practical (rarely practical). | A guide to Insect Injury of Conifers in the Lake States. USDA FS Agriculture Handbook No. 501 |
| Severe feeding by the adults may kill some shoots. This insect could cause considerable mortality in 1-5 year-old red pine plantations. |                                                                  |             |
| **Pales Weevil - *Hylobius pales*** | • Delay planting seedlings for 2 years after harvesting pines.  
• Remove freshly cut pine stumps before planting seedlings, if practical (rarely practical).  
• Treat freshly cut stumps with an insecticide if practical (rarely practical). | A guide to Insect Injury of Conifers in the Lake States. USDA FS Agriculture Handbook No. 501  
| Weevils kill seedling stems and young shoots of older trees by removing a complete ring of bark around stems or twigs. It kills first-year seedlings during moderate infestations. It can kill seedlings up to 3 years of age during heavy infestations. Though it also attacks older trees, the damage is minimal. |                                                                  |             |
| **Pine Root Collar Weevil - *Hylobius radicis*** | • On sandy soils, plant with root collar no more than one inch deep.  
• Encourage early crown closure by planting 800 or more trees per acre and increase the seedling survival rate by controlling weeds and rodents for 5 years after planting.  
• Avoid planting red pine within one mile of infested Scotch pine stands.  
• Liquidate nearby abandoned Scotch pine Christmas tree plantations. | See Red Pine Pocket Mortality below. |
# Silviculture Handbook

<td></td>
<td></td>
</tr>
</tbody>
</table>
| Pine root tip weevil - *Hylobius rhizophagus* | • Accept some damage and loss.  
• Remove jack pine from infested red pine stands.  
• Harvest merchantable trees when branches start to die.  
| Feeding on roots causes flagging, top kill and tree mortality in pole-size pines. Moderate weevil damage reduces tree growth. Red pine stands that are near Scotch pine are more vulnerable to weevil attacks. Infestation is often associated with presence of jack pine and/or nutrient-deficient, sandy soil. |                                                               |              |
| White Grubs - *Phyllophaga* spp.              | • Survey stands for white grub population before planting. If the population density is high, delay planting for one to two years.  
• Currently, there is no insecticide clearly labeled for forestry use against this insect. | • White Grubs, *Phyllophaga* spp. D. Hall. Wisconsin DNR, Division of Forestry. |
| Feeding on roots kills seedlings established for 1-3 years on sandy soils. White grub densities above 0.2 per square foot may cause heavy seedling mortality and stunting of surviving seedlings. They are common on grassy or weedy sites. |                                                               |              |
| **GALL DISEASES**                             |                                                               |              |
| Eastern Gall Rust (pine-oak gall rust) - *Cronartium quercuum* f.sp. *banksianae* | • Remove severely infected trees and branches during thinning.  
| Western Gall Rust (pine-pine gall rust) - *Peridermium harknessii* |                                                               |              |
| Eastern gall rust requires oak as an alternate host to complete its life cycle and it is considered to be widespread in Wisconsin. Western gall rust infects pine without an alternate host. Based on the survey in the 1960’s, the distribution of western gall rust is limited to north-central Wisconsin (Vilas, Oneida, Lincoln Cos.). The fungus causes swollen spherical galls on pine twigs, branches and main stems. Galls kill seedlings and branches of older trees. The disease is very common on jack pine near oaks. |                                                               |              |

</tr>
</thead>
</table>
| **Annosum Root Rot - *Heterobasidion annosum*** In Wisconsin, the disease was first confirmed in Adams Co. in 1993. As of July 2009, the disease is confirmed in 20 Counties (see FHP Figure 1 for the county distribution of this disease). Infection causes pockets of trees to develop thin crowns, reduced growth, and tree mortality. Crown symptoms typically appear 2-3 years after thinning. Pockets expand at about ½ to 1 chain every 10 – 15 years. Fruiting bodies develop at the base of infected trees. They are white and look like popcorn at an early stage, and under favorable conditions, they develop into a perennial bracket-shaped conk. A new infection site usually originates at cut stumps by spores landing on them. The fungus also spreads through root contact. | • Expect tree mortality in pockets and growth loss in trees around the pocket margin.  
• Dead trees and the bottom 8 feet of trees that are showing dieback should be left on site during thinning to avoid inadvertent disease spread.  
• Pre-salvage healthy trees 1/2 to 1 chain outside pocket perimeters to utilize the wood before the trees die. **Prevention**  
• During thinning and harvesting, start in healthy stands or areas and work in diseased areas last.  
• Apply a registered fungicide on fresh cut stumps as soon as possible after cutting or by the end of each day. Currently the use of fungicide is recommended year round throughout the state of Wisconsin.  
• Clean logging equipment with pressurized water before leaving diseased stands. | • Annosum Root Rot and Red Pine Pocket Mortality in Wisconsin; Biology and Management. 2008. Wisconsin DNR, Division of Forestry.

<tr>
<td><strong>ROOT DISEASES/DISEASE COMPLEX</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Caused by a complex of insects, fungi (<em>Leptographium</em> spp.) and insect fungal vectors. Trees weakened by root insects and fungi are later killed by bark beetles (<em>Ips</em> spp.) This complex was first identified in Wisconsin in 1975. Infected trees have reduced growth and thin crowns with yellowing, tufted needles. Pockets typically start small with one to a few dead trees surrounded by trees that have reduced shoot growth and thin crowns. Each year, a few trees on the pocket edge may die and the edge of the pocket expands. <em>Leptographium</em> spp. moves below ground through root contact and the pocket expands about 1 chain every 10 – 15 years.</td>
<td>Cut dead trees and trees that are showing dieback and/or yellowing of the foliage within and adjacent to the pocket. Cut dead trees and trees that are showing dieback and/or yellowing of the foliage, and also cut a buffer area of healthy trees around the pocket to utilize the wood before they die. There are some experimental management options. For the experimental options, please refer to the referenced management guide.</td>
